(Dated: February 1, 2008)

Abstract

Various approaches to the numerical representation of the Incomplete Gamma Function $F_m(z)$ for complex arguments z and small integer indexes m are compared with respect to numerical fitness (accuracy and speed). We consider power series, Laurent series, Gautschi's approximation to the Faddeeva function, classical numerical methods of treating the standard integral representation, and others not yet covered by the literature.

The most suitable scheme is the construction of Taylor expansions around nodes of a regular, fixed grid in the z -plane, which stores a static matrix of higher derivatives. This is the obvious extension to a procedure often in use for real-valued z .

I. OVERVIEW

A. Motivation

The Incomplete Gamma Function $F_m(z)$ is at the heart of the computation of Electron Repulsion Integrals over Gaussian-type basis functions [1, 2, 3, 4]. If these are attached to moving atoms, and the dominant part of the time dependency is kept with the bases (instead of being hidden in the expansion coefficients), the argument z is complex-valued (App. A).

With respect to the index m , we look at this as being derived from coupling of integer-valued orbital quantum numbers, whence deal only with small, non-negative m unless otherwise noted.

Several generalizations [5, 6, 7] are not considered here, except the—important—identification with some confluent hypergeometric series.

B. Contents

The explicit intention of this script is to compare a wider range of methods than proposed on the same subject before [8]. Continued fractions are not covered here, because they have already been detailed before [9, 10]. Also, the Temme and Paris approximations [11, 12] have been left aside, because they would work around the Complementary Error Function of a complex argument, the calculation of which is already of the same order of complexity as the original problem. No attempt is made to discuss the Gauss-Rys quadrature [13, 14, 15, 16] for complex z , which constructs a system of orthogonal polynomials over a finite interval with weight function $\exp(-zt^2)$; the explicit notation of its polynomial of degree 1, Eq. (2.4) by Steen et al. [17], illustrates that this also would start from the complex Error Function. Barakat [18][19, (13.3.9)] reports on z -values on the imaginary axis mapped on Bessel functions with real-valued arguments, which we do not follow on the same reasoning.

For the case of real-valued z and large m we refer the reader to the article by Takenaga [20].

$F_m(z)$ is eventually defined by an integral with a rather simple kernel. The following chapters are roughly grouped according to how much effort is spent on isolating special aspects of this kernel in exactly integrable terms, in hope of catching up the oscillations induced by $\Im z$ or the steep slopes induced for large $\Re z$, for example.

C. Fundamentals

We define $F_m(z)$ through its simplest integral representation,

$$F_m(z) \equiv \int_0^1 t^{2m} e^{-zt^2} dt = \frac{1}{2} \int_0^1 u^{m-1/2} e^{-zu} du. \quad (1)$$

Though the application in the literature often focuses on the positive real axis (as $z = x + iy$ represents some square of real-valued widths of orbital exponentials then), we will cover the general case.

Anyway, the complex-conjugate symmetry

$$F_m(\bar{z}) = \overline{F_m(z)}, \quad (2)$$

(with $\bar{z} \equiv \Re z - i\Im z$) allows us to restrict the analysis to the cases of $\Im z \geq 0$.

The forward recurrence [21][19, (6.5.21)]

$$2zF_m(z) = (2m-1)F_{m-1}(z) - e^{-z} \quad (m > \frac{1}{2}) \quad (3)$$

is a rephrasing of [19, (13.4.4)]. It suffers from cancellation of about $-\log_{10} |2z|$ ($m = 0$) and $-\log_{10} |z/m|$ ($m > 0$) decimal places when applied to $|z| \ll 1$ [22]. The corresponding backward recursion suffers from cancellation of about $-\log_{10} |(m-1/2)/z|$ decimal places, if $\Re z$ is negative and $|z|$ large. Generally speaking, the recursion allows to pick a numerically favorable m and switch to others at a small additional cost.

Further down, numerical precision is demonstrated by the number of decimal places, defined as the negative Brigg Logarithm of the relative error, $d \equiv -\log_{10} |1 - \hat{F}_m(z)/F_m(z)|$, given a high precision actual value $F_m(z)$ and its approximation $\hat{F}_m(z)$, both computed with Maple at 30 decimal places.

II. HYPERGEOMETRIC SERIES

Expansion of the exponential in (1) and term-by-term integration yields the confluent hypergeometric series (Kummer Function)

$$F_m(z) = \frac{1}{2m+1} {}_1F_1(m + \frac{1}{2}; m + \frac{3}{2}; -z); \quad (m > -1/2) \quad (4)$$

$${}_1F_1(a; a+1; z) = 1 + \frac{az}{a+1} + \cdots + \frac{az^n}{(a+n)n!} + \cdots \quad (5)$$

We start with the hypergeometric power series as a reference because there is an evident and flexible implementation with a clear numerical cost of one complex multiplication (which could be implemented with three real multiplications and five real-valued additions, or with four real-valued multiplications and two real-valued additions [23, 3.7.2]) and addition per term: one accumulates terms until the new term's contribution falls below a limit set by a preset relative error. Fig. 1 verifies that the series converges best close to the origin of the complex plane, as expected for any power series. The unexpected feature is that the series performs worse if terms are alternating—that is if z is close to the positive real axis in Fig. 1—than in the case of the non-alternating mirror point $-\bar{z}$. This is a by-product of a growth of the terms modulus up to the partial sum of index $n \approx |z| - 1$. The alternating case must overcome a massive cancellation of digits when passing this index. Consequently it needs much more terms until the partial sums approach the order of magnitude of the exact result. If measured in terms of the *absolute* error after summation of n terms, the alternating case would indeed perform better.

The Shanks transformation [24] $\epsilon_2(S_n)$ of the partial sums S_n of (5)—which is to this second order just the Aitken transformation [19, (3.9.7)]—would improve the accuracy of the plots of Fig. 1 by roughly 1.5 digits. This involves handling of finite differences between numbers that are (supposedly) already close to each other and is more tricky than the analytical transformation formulas indicate.

III. LAURENT SERIES

A. Barnes' Analysis

The asymptotically convergent Laurent series for large $|z|$ is a special case of Eq. (13.5.1) in [19] or taken from §6 in [25]:

$${}_1F_1(a; a+1; z) = \Gamma(a+1)(-z)^{-a} + \frac{ae^z}{z} \sum_{n=0}^{\infty} (1-a)_n z^{-n}, \quad (6)$$

with Pochhammer's Symbol defined as [19, (6.1.22)]

$$(b)_n \equiv \Gamma(b+n)/\Gamma(b) = \begin{cases} 1 & , (n=0) \\ b(b+1)(b+2) \cdots (b+n-1) & , (n>0) \end{cases} \quad (7)$$

FIG. 1: Contour levels of the number of valid decimal digits $d = 4 \dots 18$ of $F_m(z)$ by the power series (4) and (5), if the power series is truncated after $n = 30$ or 60 terms.

FIG. 2: Contour levels of the number of valid decimal digits $d = 2 \dots 12$ of $F_m(z)$, if the Laurent series (6) is summed up to $n = |z| + a$.

This series is also known under the label “high-T” expansion in quantum chemistry [4, 22]. The Gamma Function is not of concern since it is only needed for half-integer values, and would be tabulated based on [19, (6.1.12)]. Asymptotic convergence means that the terms in (6) shrink until $n \leq |z| + a$ and grow afterwards. This inherent limitation to the achievable accuracy is put into concrete with Fig. 2.

Swapping the the sign of z in Eq. (4), the series becomes alternating near the positive real axes of the plots in Fig. 2 for $\Re z > 0$, which leads to some obvious left-right asymmetry in the precision attained.

The contrasting regions of good convergence manifested in Fig. 2 and Fig. 1 suggest to combine these results into Fig. 3. The maximum number of terms needed this way to obtain $d = 12$ digits for $m = 0$ is $n \leq 92$ for the entire z plane (Fig. 3 top), to obtain $d = 12$ digits for $m = 1$ is $n \leq 84$ for the entire z plane (Fig. 3 middle), and to obtain $d = 17$ digits for $m = 0$ is $n \leq 166$ for the entire z plane (Fig. 3 bottom).

FIG. 3: Contour levels of the number n of terms needed to obtain an accuracy of $d = 12$ or 17 digits of $F_m(z)$, if the power series (5) and the Laurent series (6) are used complementarily.

B. Gargantini-Henrici Converging Factors

The Gargantini-Henrici analysis [26] of the converging factor of the Laurent series (6) allows a more accurate calculation of the truncated series

$$\frac{1}{z} \sum_{n=0}^{\infty} (1-a)_n z^{-n} \equiv \sum_{n=0}^{\infty} \frac{c_n}{z^{n+1}}. \quad (8)$$

The coefficients $c_n \equiv (1-a)_n$ are fed into the quotient-difference scheme easily derived from [26, Sec. 5] or taken from [27, (3.9.3)],

$$q_1^{(n)} \equiv \frac{c_{n+1}}{c_n} = 1 - a + n; \quad (n = 0, 1, 2, \dots) \quad (9)$$

$$e_k^{(n)} = k; \quad (n = 0, 1, 2, \dots) \quad (10)$$

$$q_k^{(n)} = n + k - a; \quad (n = 0, 1, 2, \dots) \quad (11)$$

and (8) is approximated by

$$\sum_{n=0}^{N-1} \frac{c_n}{z^{n+1}} + \frac{c_N}{z^{N+1}} \vartheta_N(z). \quad (12)$$

$$\vartheta_N(z) = \frac{z}{z-} \frac{q_1^{(N)}}{1-} \frac{e_1^{(N)}}{z-} \frac{q_2^{(N)}}{1-} \frac{e_2^{(N)}}{z-} \dots \quad (N = 0, 1, 2, \dots) \quad (13)$$

The following results of Fig. 4 are based on a “best knowledge” approach in the sense that the approximation (12) sums to the same $N \leq |z| + a$ as in the previous section, and that the continued fraction are accumulated until the lower indexes in $q_k^{(N)}$ and $e_k^{(N)}$ have reached N —so to recycle the same c_n that appear in the main series. (This roughly triples the number of multiplications and additions for a particular z compared to the approach of just truncating (6).)

Compared with Fig. 2, the multiplication with the convergent factor has approximately doubled the number of valid digits in a range of intermediate $|z|$, but as the rational function introduced by the continued fraction has been allowed to grow to polynomial degrees of numerator and denominator comparable to the cut-off order of the series, there is no longer a monotonic increase of accuracy away from the origin. The regions in the complex plane of predictable accuracy have got a complicated shape.

FIG. 4: Contour levels of the number of valid decimal digits $d = 6 \dots 18$ of $F_m(z)$, if the Laurent series (6) is summed up to $N = |z| + a$ and the convergent factor ϑ_N terminated as described in the text.

IV. NONSTANDARD POWER SERIES

A. Power Series of the Square

The square of the series (4) may be written with the Cauchy product formula [28, (0.316)] as

$$F_m^2(z) = \sum_{n=0}^{\infty} (-z)^n \sum_{k=0}^n \frac{1}{k!(n-k)!(2m+2k+1)(2m+2n-2k+1)} \quad (14)$$

This representation gets slightly more compact by decomposition into partial fractions and use of the symmetry $n \leftrightarrow n - k$ in the k -sum:

$$F_m^2(z) = \sum_{n=0}^{\infty} \frac{(-z)^n}{2m+n+1} \sum_{k=0}^n \frac{1}{k!(n-k)!(2m+2k+1)} \quad (15)$$

The decrease of the coefficients of this power series is demonstrated in Tab. I. The competitive power series (5) converges faster since its coefficients decrease faster, roughly $\propto 1/(n \cdot n!)$ as a function of n .

B. Power Series with Split-Off Exponential

The fundamental power series (4) is derived from replacing e^{-zt^2} by its power series; by any truncation of the series, this represents the integral kernel just at $t = 0$. We investigate a more accurate interpolation, which equals the kernel at *both* limits of the t -interval $[0, 1]$, which splits off a simpler exponential that still can be integrated exactly, and which accumulates the (smaller) remainder in a different power series:

$$e^{-zt^2} = e^{-zt} + z(t - t^2) - \frac{z^2}{2}(t^2 - t^4) + \frac{z^3}{3!}(t^3 - t^6) - \dots \quad (16)$$

$$F_m(z) = \int_0^1 t^{2m} e^{-zt} dt - \sum_{n=1}^{\infty} \frac{(-z)^n}{(n-1)!} \frac{1}{(2m+n+1)(2m+2n+1)}. \quad (17)$$

In particular,

$$F_0(z) = \frac{1 - e^{-z}}{z} - \sum_{n=1}^{\infty} \frac{(-z)^n}{(n-1)!} \frac{1}{(n+1)(2n+1)}. \quad (18)$$

As a side note, a decomposition in partial fractions and insertion of the hypergeometric notation with (4) at $m = 1$ yields

$$F_0(z) = \frac{1 - e^{-z}}{z} + z \sum_{n=0}^{\infty} \frac{(-z)^n}{n!} \frac{1}{(n+2)(2n+3)} \quad (19)$$

$$= \frac{1 - e^{-z}}{z} + z \underbrace{\sum_{n=0}^{\infty} \frac{(-z)^n}{n!} \frac{1}{n+3/2}}_{\frac{2}{3} {}_1F_1(3/2; 5/2; -z) = 2F_1(z)} - z \underbrace{\sum_{n=0}^{\infty} \frac{(-z)^n}{n!} \frac{1}{n+2}}_{\frac{1}{2} {}_1F_1(2; 3; -z) = [1 - (z+1)e^{-z}]/z^2}, \quad (20)$$

and emerges as a complicated adornment of (3). Supposed one has a fast, reliable method to compute $1 - e^{-z}$, (17) looks beneficial compared to (5) because the total power of the summation variable n in the denominator is slightly larger. Graphing the results of (18) the same way as in the two upper plots of Fig. 1, however, would yield no differences visible to the eye. Therefore we do not look into this ansatz further.

n	$\frac{1}{n+1} \sum_{k=0}^n 1/[k!(n-k)!(2k+1)]$	$\frac{1}{n+5} \sum_{k=0}^n 1/[k!(n-k)!(2k+5)]$

TABLE I: Decrease of the coefficients in (15), cases $m = 0$ and $m = 2$, as a function of n . The numbers in parentheses denote multiplication by powers of 10, e.g., for $n = 17$, we have $0.1209 \dots \cdot 10^{-11}$ and $0.791 \dots \cdot 10^{-12}$.

C. Power Series of the Half Argument

Convergence of power series is generally faster closer to the origin; the trigonometric identity $\sin^2(\omega/2) = [1 - \cos \omega]/2$ allows us to reduce the distance between z and the origin

by half if we substitute $t = \sin(\omega/2)$ in (1):

$$F_0(z) = \frac{1}{2} \int_{-1}^1 e^{-zt^2} dt = \frac{e^{-z/2}}{4} \int_{-\pi}^{\pi} e^{\frac{z}{2} \cos \omega} \cos \frac{\omega}{2} d\omega = \frac{e^{-z/2}}{4} \sum_{n=0}^{\infty} \frac{1}{n!} \left(\frac{z}{2}\right)^n \int_{-\pi}^{\pi} \cos^n \omega \cos \frac{\omega}{2} d\omega. \quad (21)$$

The auxiliary ω -integrals would be drawn from the recursion [28, (2.538.1)]

$$\int_{-\pi}^{\pi} \cos^n \omega \cos \frac{\omega}{2} d\omega = \frac{1}{n+1/2} \left[2(-)^n + n \int_{-\pi}^{\pi} \cos^{n-1} \omega \cos \frac{\omega}{2} d\omega \right]. \quad (22)$$

Since these are of the order of 1 for all n , we are left with a power series which converges $\sim z^n/(n!2^n)$, which is to be compared to $\sim z^n/(n!n)$ of (5).

The generalization to nonzero m reads

$$F_m(z) = \frac{e^{-z/2}}{4} \sum_{n=0}^{\infty} \frac{1}{n!} \left(\frac{z}{2}\right)^n \int_{-\pi}^{\pi} \sin^{2m} \frac{\omega}{2} \cos^n \omega \cos \frac{\omega}{2} d\omega. \quad (23)$$

The (n, m) -table of the ω -integrals could be generated from the table at $m = 0$ or from scratch,

$$\begin{aligned} \int_{-\pi}^{\pi} \sin^{2m} \frac{\omega}{2} \cos^n \omega \cos \frac{\omega}{2} d\omega &= \frac{1}{2^m} \sum_{k=0}^m (-)^k \binom{m}{k} \int_{-\pi}^{\pi} \cos^{k+n} \omega \cos \frac{\omega}{2} d\omega \\ &= \sum_{k=0}^m \sum_{l=0}^n \binom{m}{k} \binom{n}{l} (-)^{k+n+l} 2^{l+1} \frac{(k+l)!}{(\frac{1}{2})_{k+l+1}} \end{aligned} \quad (24)$$

The examples of Fig. 5 demonstrate that about 8 additional digits have been gained for the case $m = 0$ and $n = 30$ terms relative to the data of Fig. 1. There is no additional run-time cost since the coefficients table of (24) is static without z -dependence.

FIG. 5: Contour levels of the number of valid decimal digits $d = 4 \dots 20$ of $F_m(z)$ by the power series (23), if the power series is truncated after $n = 30$ or 40 terms. For $m = 0$ and $n = 60$, d is ≥ 19.6 in this z -domain.

V. INTERPOLATING THE INDEX

The integral (1) is solvable if $2m = 2a - 1$ is an *odd* integer [28, (2.321.2)]:

$$F_m(z) = \frac{(a-1)!}{2z^a} - \frac{e^{-z}}{2z} \left[1 + \sum_{n=1}^{a-1} \frac{(1-a)(2-a)\cdots(n-a)}{(-z)^n} \right], \quad (a = 1, 2, 3, \dots). \quad (25)$$

This could also be derived from (4) and (6), where the sum in (6) terminates if a is a positive integer.

Given z , let (25) be computed for an index set $m = 1/2, 3/2, 5/2, \dots, N + 1/2$, optionally facilitated by the index recursion [28, (2.321.1)] or (3). Let us pursue the idea that approximate values at intermediate $m = 1, 2, \dots$, which we are actually interested in, are deduced by some interpolation.

If this is done by the unique interpolating polynomial $\sum_{j=0}^N b_j m^j$ of degree N in m , the intermediate step of the calculation can formally be written down as a $(N+1) \times (N+1)$ inhomogeneous system of linear equations to get the $N+1$ unknown polynomial coefficients b_j (a Lagrange Interpolation might be cheaper numerically, though),

$$\sum_{j=0}^N m_k^j b_j = F_{m_k}(z), \quad (k = 0, 1, \dots, N; m_k = k + 1/2), \quad (26)$$

and we get for example Fig. 6. We see: (i) The method becomes more and more unreliable as $\Re z$ increases, which emerges from different weighting by the factors t^{2m} and e^{-zt^2} in the integral kernel: The derivative with respect to m multiplies the integrand (1) by $2 \ln t$. To keep the derivative small relative to $F_m(z)$ itself (and to keep $F_m(z)$ a flat function of m), it is advantageous that $t^{2m} e^{-zt^2}$ weights stronger at the right limit of the t -interval, where $\ln t$ stays small. t^{2m} becomes large near $t = 1$, whereas e^{-zt^2} is larger near $t = 0$ or $t = 1$ depending on the sign of $\Re z$.) (ii) The estimates are better close to the middle of the m interval $[\frac{1}{2}, N + \frac{1}{2}]$, which was sampled to define the interpolation polynomial, than for m close to the interval limits—which is expected for any interpolation derived from approximately equidistant sampling points.

No such interpolation polynomial of m satisfies (3) on the entire real m -axis—though the exact $F_m(z)$ does for all $m > 1/2$. Therefore one could seek after improvement of this interpolation by enforcing some compliance with (3). Test calculations were made following the strategy that one or more lines in the system of linear equations (26) are replaced by

FIG. 6: Contour levels of the number of valid decimal digits $d = 1 \dots 9$ of $F_1(z)$ and $F_4(z)$ by interpolation of the index with a polynomial of degree $N = 8$ or 4 in m , Eq. (26).

coupling some of the unknown $F_m(z)$ via (3), in concrete

$$\sum_{j=0}^N [2zm_u^j - (2m_u - 1)m_v^j] b_j = -e^{-z}, \quad (m_v = 0, 1, 2, \dots; m_u = m_v + 1). \quad (27)$$

The polynomial that ensues does no longer hit the $F_{m_k}(z)$ that was thrown out, but follows (3) for those m_u brought in. Results of this ansatz with $N = 4$, removal of $F_{9/2}$ from the set of interpolated points, and introduction of the $m_v = 1 \leftrightarrow m_u = 2$ coupling with (27) add at most about half a digit of accuracy to what is already shown in Fig. 6. There is no further improvement if the line for $F_{7/2}$ in (26) is also removed to add the line (27) for the $m_v = 2 \leftrightarrow m_u = 3$ coupling.

Furthermore one would try to add known information on the first derivatives with respect to m to enhance the quality of the polynomial interpolation. Unfortunately, even the simplest case of $\partial F_m(z)/\partial m$ at $m = 1/2$ would demand computation of the Exponential Integral $E_1(z)$ [29],

$$\left. \frac{\partial F_m(z)}{\partial m} \right|_{m=1/2} = -\frac{1}{2z} [E_1(z) + \gamma + \log(z)]. \quad (28)$$

This infects also the partial derivatives at $m = 3/2, 5/2, \dots$

$$\frac{\partial}{\partial m} F_m(z) = \frac{1}{z} F_{m-1}(z) + \frac{m - 1/2}{z} \frac{\partial}{\partial m} F_{m-1}(z); \quad (m > 1/2). \quad (29)$$

Another attempt of refinement is to acknowledge the simple poles at the negative half integers of m . Test calculations with the modified separation ansatz [30] $F_m(z) \approx (\sum_{j=0}^N b_j m^j)/(2m+1)$, which manifests the pole at $m = -1/2$, and again a numerator polynomial of degree $N = 4$ result in changes of up to one digit (in both directions) compared to the bottom graph in Fig. 6.

In summary, it seems to be difficult to bridge the gap between F_m at half integer and integer m through interpolation.

VI. GENERIC METHODS OF INTEGRATION

A. Local Taylor Expansions in the Integration Interval

1. Expansion of the Exponential

The “global” first approximation of the integrand in Sec. IV B may be pushed one notch further towards a brute-force numerical method by slicing the t -interval $[0, 1]$ into N same size subintervals of half-width $\Delta \equiv 1/(2N)$, centered at $t_l = (2l - 1)/\Delta$ ($l = 1, \dots, N$). In each of these subintervals, $\exp(-zt^2)$ is approximated by its Taylor series around t_l . The derivatives are [19, (7.1.19)]

$$\left(\frac{d}{dt}\right)^n e^{-zt^2} = (-)^n z^{n/2} H_n(\sqrt{z}t) e^{-zt^2}, \quad (30)$$

in terms of Hermite Polynomials H_n —looking at the exponential as the first derivative of the error function—, whence the Taylor series

$$e^{-zt^2} = \sum_{n=0}^{\infty} \frac{1}{n!} (t - t_l)^n (-)^n z^{n/2} H_n(\sqrt{z}t_l) e^{-zt_l^2}. \quad (31)$$

$F_0(z)$ is the Riemann sum over the subintervals

$$F_0(z) \approx \sum_{l=1}^N \int_{t_l-\Delta}^{t_l+\Delta} dt e^{-zt^2} = 2 \sum_{l=1}^N e^{-zt_l^2} \sum_{n=0,2,4,\dots}^{\infty} \frac{\Delta^{n+1}}{(n+1)!} z^{n/2} H_n(\sqrt{z}t_l) \quad (32)$$

Fig. 7 shows the accuracy of (32) for two N , keeping the polynomial expansion only up to some degree n .

The two graphs in Fig. 7 with degrees kept up to $n = 6$ show the two spots at $z \approx 2.80$ and $z \approx 7.02$ with higher precision than their surroundings. This is part of a more general phenomenon, in which for some z the positive and negative lobes of the Hermite Polynomials are sampled with best effective cancellation. This generates one such spot at $z \approx 4.08$ ($n \leq 4$), those two for $n \leq 6, \dots$

On the computational expense: as the formula requires Hermite polynomials of even indexes only, there is no need to compute the $\sqrt{z}$ and no gain using their recursion formulas. Two (complex) multiplications compute zt_l^2 . Each H_n is a polynomial of degree $n/2$ in this combined variable, which costs $n/2$ multiplications and $n/2$ additions with the Horner scheme. The powers of Δ are fixed, and there are about 3 multiplications for each term in

FIG. 7: Contour levels of the number of valid decimal digits $d = 8 \dots 16$ of $F_0(z)$, if the series (32) is used with $N = 10$ or 20 subintervals and if the Hermite Polynomials are included up to degree $n = 6$ or 8 . Note that in a region of $\Re z \gtrsim 8$ and small $|\Im z|$ an increase of n from 6 to 8 decreases the accuracy.

n , plus one (complex) exponential. This is to be multiplied by N . This totals at least $16N$ multiplications if n runs up to 6, and so only the lowermost picture in Fig. 7 would be part of a fair comparison with the other competitive approaches.

2. Expansion of the Algebraic Factor

In a similar manner as above, one could expand the algebraic factor $u^{m-1/2}$ of (1) in Taylor series around $u_l \equiv (2l-1)/\Delta$ to end up with closed form integrals. To second order,

$$u^{m-1/2} \approx u_l^{m-1/2} + (m - \frac{1}{2})u_l^{m-3/2}(u - u_l) + (m - \frac{1}{2})(m - \frac{3}{2})u_l^{m-5/2}\frac{(u - u_l)^2}{2}, \quad (33)$$

and the Riemann sum

$$F_m(z) \approx -\frac{1}{2z} \sum_{l=1}^N e^{-zu_l} u_l^{m-1/2} \left\{ e^{-z\Delta} - e^{z\Delta} + \frac{m-1/2}{zu_l} [e^{-z\Delta}(1+z\Delta) - e^{z\Delta}(1-z\Delta)] \right. \\ \left. + \frac{(m-1/2)(m-3/2)}{(zu_l)^2} \left[e^{-z\Delta}(\frac{z^2\Delta^2}{2} + z\Delta + 1) - e^{z\Delta}(\frac{z^2\Delta^2}{2} - z\Delta + 1) \right] \right\}.$$

This achieves up to $d = 2.6$ decimals ($m = 0$, $N = 20$), $d = 5.4$ ($m = 1$, $N = 20$), $d = 5.8$ ($m = 1$, $N = 40$), and $d = 8.2$ ($m = 2$, $N = 40$) in the z -domain as in Fig. 7. (These numbers refer to the “lower left” corner of the z -region, and are a few digits worse in the opposite corner.)

The main obstacle to higher performance is the poor fit of (33) close to $u = 0$. We may patch this by replacing the contribution in this subinterval, the term $l = 1$ where $0 \leq u \leq 2\Delta$ remains small, by the associated power series of the exponential,

$$F_m(z) \approx -\frac{1}{2z} \sum_{l=2}^N e^{-zu_l} u_l^{m-1/2} \left\{ \dots \right\} + \frac{(2\Delta)^{m+1/2}}{2} \sum_{n=0,1,2,\dots} \frac{(-2z\Delta)^n}{(m+1/2+n)n!}. \quad (34)$$

With this ansatz and the sum over n kept up to $n = 3$, the maximum number of digits in the z -domain as in Fig. 7 rise to $d = 7.8$ ($m = 1$, $N = 40$), and $d = 10.4$ ($m = 2$, $N = 40$).

B. Fourier Expansion of the Algebraic Integral Kernel

A Fourier expansion of the algebraic term in (1)

$$u^{m-1/2} = \sum_{l=0}^{\infty} c_l \cos(lu \frac{\pi}{2}) \quad (35)$$

m	N		
	512	256	128
1	(-2)3.6	(-2)5.1	(-2)7.4
2	(-5)4.6	(-4)1.3	(-4)3.7
3	(-6)8.2	(-5)3.5	(-4)1.4

TABLE II: Typical maximum deviation between the left hand side and the right hand side of (35) in the interval $u \in [0, 1]$, if one period of $f(u)$ is sampled by N points and the sum (35) limited to $0 \leq l \leq N/2$. Numbers in parentheses are powers of 10 as in Tab. I.

offers the series

$$\int_0^1 u^{m-1/2} e^{-zu} du = \frac{1 - e^{-z}}{z} + 2 \sum_{l=1,3,5,\dots}^{\infty} c_l \frac{2z + (-)^{[l/2]} l \pi e^{-z}}{(2z)^2 + (l\pi)^2}, \quad (36)$$

where $c_0 = 1$ and $c_2 = c_4 = c_6 = \dots = 0$ have already been assumed. To reduce any Gibbs oscillations [31] of (35) at the ends of the interval $[0, 1]$, $u^{m-1/2}$ is embedded into the even, 4-periodic, and steady carrier function $f(u) \equiv u^{m-1/2}$ for $u \in [0, 1]$, $f(u) \equiv 2 - (2 - u)^{m-1/2}$ for $u \in [1, 2]$, $f(u) \equiv f(2 - u)$ and $f(u) = f(u + 4)$ elsewhere. (Obviously, the singularity at $u = 0$ reduces the quality of this approach right from the start if $m = 0$.) The c_l are approximated by a discrete cosine transform on N grid points

$$c_j = \frac{4}{N} \left[(-)^j + \sum_{k=1}^{N/2-1} f(4k/N) \cos(2\pi \frac{jk}{N}) \right] \quad (j = 1, 2, \dots, N/2), \quad (37)$$

and the summation (36) is truncated at $l = N/2$. The c_l would be kept in constant tables since they do not depend on z , and the cost of evaluating (36) amounts to about $N/4$ evaluations of the rational term. Fig. 8 shows that for moderately small m a precision of just of the order of 5 digits result from this type of evaluation, which is not efficient compared to other methods proposed here. This is ultimately a progression of residual fitting errors (Gibbs oscillations) which remain rather large close to $u = 0$ and $u = 1$ (Tab. II).

In the special case where one would like to tabulate $F_m(z)$ along some fixed ordinate $\Re z = \text{const}$ in equidistant steps of $\Im z$, one could draw a lot of additional benefit from the inherent parallelism of Fast Fourier Transform techniques applied to the decomposition

$$F_m(z) = \frac{1}{2} \int_0^1 u^{m-1/2} e^{-\Re zu} e^{-i\Im zu} du. \quad (38)$$

This seems to be too special to be put into detail here.

FIG. 8: Contour levels of the number of valid decimal digits $d = 1.5 \dots 8$ of $F_m(z)$, if the Fourier series (36) is used with $N = 256$ or 512 abscissa points of the Fourier interpolation.

C. Taylor series in the complex z -Plane

With [19, (13.4.9)], the complex derivatives of $F_m(z)$ are equivalent to ladder-type operation with respect to m and a :

$$\left(\frac{d}{dz}\right)^n {}_1F_1(a; a+1; z) = \frac{a}{a+n} {}_1F_1(a+n; a+1+n; z), \quad (39)$$

$$\left(\frac{d}{dz}\right)^n F_m(z) = (-)^n F_{m+n}(z) \quad (40)$$

This close link between the index and the higher derivatives means that one may tabulate the expansion coefficients of the Taylor series

$$F_m(z_0 + \varepsilon) = F_m(z_0) - \varepsilon F_{m+1}(z_0) + \frac{\varepsilon^2}{2!} F_{m+2}(z_0) + \cdots + \frac{(-\varepsilon)^n}{n!} F_{m+n}(z_0) + \cdots \quad (41)$$

anchored at some z_0 in the complex plane for all m at the same time. This keeps these tables smaller than for any function with decoupled index and argument. Despite the fact that these tables need to contain complex values and need to be arranged on a 2D grid in the complex plane, there is no inherently new aspect over what is already assessed in the literature for real z [21]. Chebychev approximations in the complex case could be derived by expanding $(-\varepsilon)^n$ in a sum over products of $\Re \varepsilon$ and $\Im \varepsilon$, normalization to the interval $[-1, 1]$ and independent progression for the real and imaginary part as described in [19, §22.20].

Fig. 9 is an example where the nodes span the $\Re z_0$ interval from -33 to 18 with a stride of $s = 3$, and $\Im z_0$ the interval from 0 to 36 also with a stride of $s = 3$:

$$z_0 = ks + ils \quad (k = -11, -10, \dots, 6; l = 0, 1, \dots, 12) \quad (42)$$

Up to 23 terms need to be accumulated in (41) to calculate $F_0(z)$ if z falls inside this finite grid's domain; values outside are handled with Eq. 6. This term count is stored as entry 23 at $m = 0$ and $d = 14$ in the upper part of Tab. III. A free entry in the table indicates, what could not be computed if the tabulated $F_j(z)$ would be limited to $j \leq 30$, which would be less than $m+n$ for this slot. The lower part of the table illustrates, how a three times denser grid of nodes cuts down on the worst case convergence, as it reduces the maximum distance $|\varepsilon|$ to the nearest z_0 from $3/\sqrt{2}$ to $1/\sqrt{2}$. This necessitates a ninefold larger static table, unless one uses the smaller number of terms to reduce the maximum index j of tabulated F_j .

FIG. 9: The number n of terms in the Taylor series Eq. (41) to achieve $d = 14$ digits of accuracy of $F_0(z)$.

m	d				
	12	14	15	16	17
0	21	23	24	25	26
1	21	23	24	25	26
3	21	23	24	25	26
5	21	23	24	25	

m	d				
	12	14	15	16	17
0	14	16	17	17	18
1	14	16	16	17	18
5	14	15	16	17	18

TABLE III: The upper table shows the maximum number of terms needed for nearest neighbor Taylor expansions (41) as a function of m and accuracy d on a support grid with spacing 3 in the z plane. The lower table illustrates the case of a denser spacing of 1.

On a side note, (41) could be rewritten similar to [32, (2.1)]

$$F_m(z_0 + \varepsilon) = e^{-z_0} F_m(\varepsilon) + z_0 \sum_{n=0}^{\infty} \frac{1}{m + 1/2 + n} \frac{(-\varepsilon)^n}{n!} F_{m+1+n}(z_0), \quad (43)$$

using (3) once for each term, or integrating (1) by parts.

D. Gauss-Jacobi quadrature

As considered by Gautschi [33] for a more general case, (1) is readily accessible by a Gauss-Jacobi quadrature,

$$F_m(z) \approx \sum_{i=1}^n w_i e^{-zt_i^2}. \quad (44)$$

Weights w_i and abscissae t_i are discussed in App. E.

Fig. 10 demonstrates that this method is most robust at small $|z|$, which is expected since the Gauss quadrature effectively approximates $\exp(-zt^2)$ by a polynomial of degree $2n$ in t . The numerical expense roughly adds up to n computations of exponentials $\exp(-zt_i^2)$. This is cheaper than evaluation of (32) at the same $N = n$; by further comparison of Fig. 10 with Fig. 7 we conclude that the Gauss-Jacobi ansatz proposed here is superior to the method of Sect. VI A.

The drawback by further comparison with the reference calculation of Sec. II is that each complex exponential needs much more CPU time than a complex multiplication. Tests with the C++ implementation by the Sun Forte Developer 7 Collection suggest a factor of about twenty.

This is also the reason why the trapezoidal rule, and higher rules like the Simpson Rule which follow from a Richardson extrapolation, have been kept aside in this manuscript.

E. Cubic Spline Interpolation

The exponential of (1) could be approximated by cubic splines in N subintervals $[t_j, t_j + 1/N]$ ($j = 0, \dots, N-1$) which cover the t -interval, to yield a sum over elementary integrals,

$$F_m(z) \approx \sum_{j=0}^{N-1} \int_{t_j}^{t_{j+1}} t^{2m} [c_0 + c_1 t + c_2 t^2 + c_3 t^3] dt. \quad (45)$$

In each of these intervals, the four coefficients c_i are defined by demanding that the cubic polynomial fit and its first derivative equal the exponential and its first derivative at both limits, t_j and t_{j+1} :

$$\begin{pmatrix} 1 & t_j & t_j^2 & t_j^3 \\ 1 & t_{j+1} & t_{j+1}^2 & t_{j+1}^3 \\ 0 & 1 & 2t_j & 3t_j^2 \\ 0 & 1 & 2t_{j+1} & 3t_{j+1}^2 \end{pmatrix} \begin{pmatrix} c_0 \\ c_1 \\ c_2 \\ c_3 \end{pmatrix} = \begin{pmatrix} e^{-zt_j^2} \\ e^{-zt_{j+1}^2} \\ -2zt_j e^{-zt_j^2} \\ -2zt_{j+1} e^{-zt_{j+1}^2} \end{pmatrix} \quad (46)$$

FIG. 10: Contour levels of the number of valid decimal digits $d = 3 \dots 19$ of $F_m(z)$ by (44), if the order of the Gauss-Jacobi quadrature is $n = 10$ or 20.

FIG. 11: Contour levels of the number of valid decimal digits $d = 1 \dots 8$ of $F_m(z)$ by the spline interpolation (45) for $N = 10$ subintervals. One would gain one digit throughout this z region by increasing N to 20. The accuracy for $m = 3$ would be a few digits lower.

The number of multiplications to solve this system of linear equations in each interval looks prohibitive, even though one would recycle the matrix elements and right hand sides, and even though the matrix is already close to triangular form. One must evaluate N exponentials and insert the c_i into about $2N$ polynomials of degree $2m + 4$ to finalize (45). Actually, inserting (46) into (45) yields rather tight formulas (see [34] and App. D), namely

$$F_0(z) \approx \sum_{j=0}^{N-1} \frac{t_{j+1} - t_j}{6} \left[(3 + zt_{j+1}(t_{j+1} - t_j)) e^{-zt_{j+1}^2} + (3 - zt_j(t_{j+1} - t_j)) e^{-zt_j^2} \right] \quad (47)$$

and

$$F_1(z) \approx \sum_{j=0}^{N-1} \frac{t_{j+1} - t_j}{30} \left[(2zt_{j+1}^4 - zt_{j+1}^2 t_j^2 + 8t_{j+1}^2 + 5t_{j+1} t_j - zt_{j+1} t_j^3 + 2t_j^2) e^{-zt_{j+1}^2} + (2zt_j^4 - zt_{j+1}^2 t_j^2 + 8t_j^2 + 5t_{j+1} t_j - zt_{j+1}^3 t_j + 2t_{j+1}^2) e^{-zt_j^2} \right]. \quad (48)$$

The drawback formulated in Sec. VID, however, remains: we consider only very small N , and conclude from Fig. 11 that this numerical expenditure is too high to consider this method a competitive candidate.

F. Salzer's Numerical Inverse Laplace Transform

$F_m(z)$ can be written in terms of the inverse Laplace Transform of some function $P(m + 1/2, z)$ which is loosely related to the χ^2 probability distribution [11]:

$$F_m(z) = \frac{\Gamma(a)}{2z^a} P(a, z); \quad (a \equiv m + 1/2), \quad (49)$$

where

$$P(a, z) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} e^{zs} \frac{1}{s(s+1)^a} ds; \quad (c > 0). \quad (50)$$

The binomial expansion of $(s+1)^a$ in powers of $1/s$ and interchange of integration and summation transforms (50) to the power series defined by (4) and (5).

Substituting $zs \equiv p$ in $P(a, z)$, (50) is in shape for Salzer's [35] approximation of the kernel $1/[s(s+1)^a]$ by polynomials in $1/p$.

(49) and (50) assume the existence of the Laplace Transform of $z^a F_m(z)$; this limits this proposal in general to $\Re z > 0$ as indicated by the factor e^z in (6) and made explicit in [36, p. 341]. Therefore we use [11]

$$P(a, z) = 1 - Q(a, z) = 1 - ae^{-z} z^a \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} e^{as} \frac{1}{(as)^a} \frac{1}{z - as} ds \quad (51)$$

to complement for $\Re z < 0$. This, however, is of purely experimental nature since (51) depends on a contour integration passing between the pole and the branch point, and this is not at all accounted for in Salzer's sampling of the complex p -plane.

Sample outputs of this approach are gathered in Fig. 12 using abscissa and weights as tabulated in Tab. IV. The discontinuity in the graphs at passing the imaginary z -axis is due to switching between (50) and (51). We see that the accuracy of $F_1(z)$ rises by about one decimal if the number n of evaluations of the kernel is increased from 16 to 30, but the rise in the case $F_4(z)$ —not demonstrated in the figure—is only about a third decimal. The major difference to the Taylor and Lauren series methods of sections II, III A and VI C is that this here still demands computation of a complex valued root for each of the sampling points, and that prediction of the accuracy both as a function of m and z is complicated.

Finally, we did not try to apply this approximation to the Laplace transform of F_m itself, because sampling that kernel, put into concrete in App. B, demands calculation of a complex-valued inverse trigonometric function, which is a costly numerical task.

FIG. 12: Contour levels of the number of valid decimal digits $d = 2 \dots 9$ of $F_m(z)$, if $n = 16$ or 30 sampling points are used in Salzer's integration of the inverse Laplace transform (50).

TABLE IV: Extension of Salzer's [35] table of reciprocals of the zeros of $P_n(x)$ and Christoffel Numbers $A_i^{(n)}$ to the case $n = 16$. Numbers in parentheses are powers of 10 as in Tab. I. Half of the values are not shown and follow by complex conjugation: $1/p_i^{(n)} = 1/\overline{p_{i-1}^{(n)}}$, $A_i^{(n)} = \overline{A_{i-1}^{(n)}}$, ($i = 2, 4, 6, \dots, n$).

VII. RELOCATION TO OTHER SPECIAL FUNCTIONS

A. Gautschi's approach to the Faddeeva Function

Following [9, 37] and Chapt. 7.1 of [19], F_0 is related to the complex error function via

$$F_0(z) = \frac{\sqrt{\pi}}{2} \frac{\operatorname{erf}(\sqrt{z})}{\sqrt{z}}, \quad (52)$$

and to the Faddeeva function w as

$$F_0(z) = \frac{1}{2} \sqrt{\frac{\pi}{z}} [1 - e^{-z} w(i\sqrt{z})]. \quad (53)$$

According to [37, (2.14)][19, (7.1.4)][19, (7.1.15)], w has the following representation in terms of weights $\lambda_k^{(n)}$ and abscissae $t_k^{(n)}$ of the n -point Hermite Gauss Integration (see App. C):

$$w(z) \approx \frac{\pi}{i} \sum_{k=1}^n \frac{\lambda_k^{(n)}}{z - t_k^{(n)}}. \quad (54)$$

The computation needs only about $n/2$ complex divisions and additions, since the weights and abscissa group in symmetric pairs:

$$w(z) \approx \frac{2\pi}{i} z \sum_{t_k^{(n)} > 0} \frac{\lambda_k^{(n)}}{z^2 - (t_k^{(n)})^2}. \quad (55)$$

Fig. 13 considers the application with $n = 20$ or 32 . This approach here targets the same region covered by Fig. 2, either large $\Re z$ or large $\Im z$, but is obviously superior, since it first is scalable through the choice of n , and at a comparable investment into the number of complex operations it achieves the more accurate results.

Eq. (2.1) in the work by Chiarella and Reichel [38] looks similar to (55): roughly speaking, the $t_k^{(n)}$ are replaced by equidistant nh , and the $\lambda_k^{(n)}$ by $\exp(-n^2 h^2)$.

Strand [39] proposed a method to compute the complementary error function of z , if $\Im z$ is small. It starts from the presumably known complementary error function of $\Re z$, and therefore is too special to be treated here.

B. Expansion in Modified Spherical Bessel Functions

The Confluent Hypergeometric Function in (4) may be expanded in terms of Modified Spherical Bessel Functions [19, (13.3.6)][40], which may be rewritten with [19, (10.2.24)] to

FIG. 13: Contour levels of the number of valid decimal digits $d = 5 \dots 19$ of $F_0(z)$, if the order of the Hermite Polynomial in (54) is 20 or 32.

give

$${}_1F_1(a; a+1; 2z) = e^z \sqrt{\frac{2\pi}{z}} \sum_{n=0}^{\infty} (-1)^n \left(\frac{1}{2} + n \right) \frac{(1-a)_n}{(1+a)_n} I_{n+1/2}(z) \quad (56)$$

$$= \sum_{n=0}^{\infty} (-1)^n (2n+1) \frac{(1-a)_n}{(1+a)_n} e^z z^n \left(\frac{1}{z} \frac{d}{dz} \right)^n \frac{\sinh z}{z} \quad (57)$$

n	$e^z z^n \left(\frac{1}{z} \frac{d}{dz}\right)^n \frac{\sinh z}{z}$
0	$[A - 1]/[2z]$
1	$[z(A + 1) - (A - 1)]/[2z^2]$
2	$[(z^2 + 3)(A - 1) - 3z(A + 1)]/[2z^3]$
3	$[(z^3 + 15z)(A + 1) - (6z^2 + 15)(A - 1)]/[2z^4]$
4	$[(z^4 + 45z^2 + 105)(A - 1) - (10z^3 + 105z)(A + 1)]/[2z^5]$
5	$[(z^5 + 105z^3 + 945z)(A + 1) - (15z^4 + 420z^2 + 945)(A - 1)]/[2z^6]$
6	$[(z^6 + 210z^4 + 4725z^2 + 10395)(A - 1) - (21z^5 + 1260z^3 + 10395z)(A + 1)]/[2z^7]$

TABLE V: Complexity evaluating the terms in (57) for small values of n , with $A \equiv \exp(2z)$.

with $a \equiv m + 1/2$. Note that a factor $(b - a - \frac{1}{2} + n)$ was missing in (13.3.6) of early editions of [19]. The individual terms are

$$e^z \sqrt{\frac{2\pi}{z}} (-)^n \left(\frac{1}{2} + n\right) \frac{(1-a)_n}{(1+a)_n} I_{n+1/2}(z) \propto \frac{(-)^n}{(2n-1)!!} \frac{(1-a)_n}{(1+a)_n} (z^n + z^{n+1}) + O(z^{n+2}), \quad (58)$$

which indicates (i) that a direct implementation based on the formulas of Tab. V may suffer from severe cancellation of digits if $|z|$ is small, and (ii) that the recurrence relations [19, (10.2.12)] must be used in the downward direction, for example as outlined in [41]. Table V shows that already for a small number of terms used to approximate the series, a considerable number of complex polynomials must be computed. Fig. 14 indicates that the convergence of the series is good close to the origin of the complex plane (explained by the fact that the lowest order terms of the Taylor series (58) are $O(z^n)$).

The assessment follows the conclusion in [3] for a similar expansion that was a hybrid of the Dawson and the error function for real z : Since the evaluation of the Bessel Functions would be of similar complexity as a straight-forward power series for small $|z|$, and since the convergence is slow for large $|z|$, this type of ansatz is not competitive.

C. Dijkstra's continued fractions

According to Dijkstra [42], the constraint that (5) and (6) serve well only inside domains of small or large modulus may be overcome by use of an auxiliary function K that allows a

FIG. 14: Contour levels of the number of valid decimals $d = 3 \dots 12$ of $F_m(z)$, if the series (57) is truncated after the term $n = 7$, for $m = 5$ and $m = 1$.

suitable continued fraction

$$K(a, b, z) \equiv \frac{{}_1F_1(a; b+1; z)}{b {}_1F_1(a; b; z)} = \frac{1}{b+z-} \frac{z(b+1-a)}{b+1+z-} \dots \frac{z(b+n-a)}{b+n+z-} \dots \quad (59)$$

Application to (4) with ${}_1F_1(a; a; -z) = e^{-z}$ proposes

$$F_m(z) = \frac{1}{2} e^{-z} K(a, a, -z), \quad (a \equiv m + 1/2). \quad (60)$$

In Fig. 15 we investigate the readiness of the representation. It is excellent nearby the negative real axis, staying above $d = 10$ ($m = 3, N = 16$), $d = 13.1$ ($m = 1, N = 32$) and $d = 16.6$ ($m = 3, N = 32$). Dijkstra [42] demonstrates that $K(a, b, z)$ mediates between low- z and high- z expansions for real positive z . In so far, the sign change of z in (60) means our plot actually looks at the “wrong” side. The continued fraction is terminated at the N th convergent. About one decimal in accuracy has actually be gained by deletion of the z in this closing denominator like

$$K(a, a, z) = \frac{1}{a + z -} \frac{z}{a + 1 + z -} \cdots \frac{Nz}{a + N}. \quad (61)$$

A combination of [19, (13.4.4)], the Kummer transformation [19, (13.1.27)] and the definition (59) enforces that both arguments of z carry the same sign:

$$zK(1, a, z) = 1 - \frac{e^{-z}}{(2m-1)F_{m-1}(z)} \quad (62)$$

Fig. 16 shows that this indeed extends the fitness of this Dijkstra representation into the region of $\Re z > 0$, at the expense of the fitness to compute $F_m(z)$ at $\Re z < 0$.

FIG. 15: Contour levels of the number of valid decimal digits $d = 1 \dots 16$ of $F_m(z)$, if Dijkstra's representation (60) is used with (61) truncated at a depths N .

FIG. 16: Contour levels of the number of valid decimal digits $d = 1 \dots 18$ of $F_m(z)$, if Eq. (62) is used with Dijkstra's continued fraction (59) truncated at a depths N .

VIII. SUMMARY

Working with standard numerical methods on the fundamental integral representation of the Incomplete Gamma Function $F_m(z)$ is generally inefficient as it demands dense sampling (frequent evaluation) of complex exponentials.

Continued fraction and rational function approximations are difficult to control, because the regions of known accuracy in the z -plane are complicated.

Being an analytic function of z , the fastest evaluation uses Taylor series which recall tables of the derivatives $d^n F_m(z_0)/dz_0^n$ that have been computed off-line to high precision (Sec. VIC).

APPENDIX A: EXAMPLE APPLICATION: TRAVELLING ORBITALS

Let $\Psi_0(\mathbf{r}, t) = \exp(i\omega t)\varphi_0(\mathbf{r})$ be a solution of the Schrödinger equation

$$\left[-\frac{\hbar^2}{2m}\nabla^2\mathbf{r} + V(\mathbf{r})\right]\Psi_0(\mathbf{r}, t) = -i\hbar\frac{\partial}{\partial t}\Psi_0(\mathbf{r}, t) \quad (\text{A1})$$

associated with a stationary potential $V(\mathbf{r})$. The transition to a potential that moves with constant velocity $\mathbf{v}$ in the laboratory system is useful to describe electrons bound to scattering atoms, and reads

$$\left[-\frac{\hbar^2}{2m}\nabla^2\mathbf{r} + V(\mathbf{r} - \mathbf{v}t)\right]\Psi_{\mathbf{v}}(\mathbf{r}, t) = -i\hbar\frac{\partial}{\partial t}\Psi_{\mathbf{v}}(\mathbf{r}, t) \quad (\text{A2})$$

The solution

$$\Psi_{\mathbf{v}}(\mathbf{r}, t) = \exp(i\omega t) \exp(i\frac{\hbar^2 k^2}{2m}t) \exp(-i\mathbf{k} \cdot \mathbf{r}) \varphi_0(\mathbf{r} - \mathbf{v}t) \quad (\text{A3})$$

with $\hbar\mathbf{k} \equiv m\mathbf{v}$ is generated from the solution of (A1) [43]. This Galilean transformation lets “travelling” orbitals $\propto \exp(-i\mathbf{k} \cdot (\mathbf{r} - \mathbf{R}))\varphi_0(\mathbf{r} - \mathbf{R})$ become a natural choice for basis functions in the laboratory coordinate system [44]. If the φ_0 are linear combinations of Gaussian Type Orbitals (GTO’s), the Coulomb Integrals may be treated with the product rule for GTO’s [1, 2, 4, 15, 45, 46, 47, 48, 49, 50], and the Gauss transform

$$\frac{1}{r} = \frac{2}{\sqrt{\pi}} \int_0^\infty e^{-r^2 s^2} ds \quad (\text{A4})$$

of the Coulomb potential eventually reduces the Coulomb integrals to Incomplete Gamma Functions with complex argument z [51, 52, 53].

APPENDIX B: LAPLACE REPRESENTATION

Laplace transformation of the power series (4) on a term-by-term basis yields [28, (7.621.4)]

$$\mathcal{L}(F_m(z)) \equiv \int_0^\infty e^{-zs} F_m(z) dz = \frac{1}{2a} \frac{1}{s} {}_2F_1(a, 1; a+1; -\frac{1}{s}) = \sum_{n=1}^\infty \frac{(-)^{n+1}}{2(a+n-1)s^n} \quad (\text{B1})$$

$$= \frac{1}{(\sqrt{s})^{1-2m}} \sum_{n=1}^\infty \frac{(-)^{n+1}}{2m+2n-1} \frac{1}{(\sqrt{s})^{2m+2n-1}} \quad (\text{B2})$$

$$= s^{a-1} \left[(-)^{m+1} (\arctan \sqrt{s} - \frac{\pi}{2}) + \sum_{k=1}^m \frac{(-)^{k+1}}{(2k-1)s^{k-1/2}} \right] \quad (\text{B3})$$

where $a \equiv m + 1/2$. This result could also be derived from the Laplace transform of the differential equation—which is a combination of (40) and (3)—:

$$z \frac{d}{dz} F_m(z) = -z F_{m+1}(z) = -a F_m(z) + \frac{e^{-z}}{2}, \quad (\text{B4})$$

$$-\frac{d}{ds} [s(\mathcal{L}F_m)(s) - F(z=0)] = -a(\mathcal{L}F_m)(s) + \frac{1}{2} \frac{1}{s+1}. \quad (\text{B5})$$

This inhomogeneous differential equation

$$s \frac{d}{ds} (\mathcal{L}F_m)(s) = (a-1)(\mathcal{L}F_m)(s) - \frac{1}{2} \frac{1}{s+1} \quad (\text{B6})$$

is solved by writing down the solution of the separable homogeneous differential equation, $\mathcal{L}F_m(s) = s^{a-1}c$, then introducing the function $c(s)$ for the constant c , which leaves a simple differential equation for $dc(s)/ds$ and

$$c(s) = \int \frac{1}{s^a(s+1)} ds. \quad (\text{B7})$$

This is solved with the recursion [28, (2.249)], because a is half integer, until [28, 2.211] is applicable for the reduced remnant.

To round off this excursion: One could introduce [19, (4.4.42)]

$$\arctan \alpha = \frac{\alpha}{1+\alpha^2} \left[1 + \frac{2}{3} \frac{\alpha^2}{1+\alpha^2} + \frac{2 \cdot 4}{3 \cdot 5} \left(\frac{\alpha^2}{1+\alpha^2} \right)^2 + \cdots + \frac{(2n)!!}{(2n+1)!!} \left(\frac{\alpha^2}{1+\alpha^2} \right)^n + \cdots \right] \quad (\text{B8})$$

in (B3), the simplest case of $m = 0$ reading

$$\mathcal{L}(F_0(z)) = -\frac{1}{1+s} \left[1 + \frac{2}{3} \frac{s}{1+s} + \cdots + \frac{(2n)!!}{(2n+1)!!} \left(\frac{s}{1+s} \right)^n + \cdots \right] + \frac{\pi}{2} \frac{1}{\sqrt{s}}. \quad (\text{B9})$$

Truncation of this series after some n th term followed by an inverse Laplace transform [19, (29.2.21)] yields e^{-z} multiplied by a polynomial of degree n in z , plus $\sqrt{\pi/z}/2$, i.e., replaces $w(i\sqrt{z})/\sqrt{z}$ in (53) by a polynomial in z . Obviously, that is a poor representation, as it forces the polynomial in z to compensate the singularity at $z = 0$.

APPENDIX C: ROOTS OF HERMITE POLYNOMIALS

These pairs of weights and abscissa of the Gauss-Hermite quadrature can be taken from [19, (Tab. 25.10)] for some values of $n \leq 20$, for $n = 8, 16, 32$ or 64 from [54], or otherwise computed with the `d01bcf` routine of the NAG library. Following on a reference by Shao

et al. [54] to a note by Hofsommer [55], the zeros of $H_n(x)$ can be refined through a third order Newton method. Improved solutions $x^{(j+1)}$ are computed from guesses $x^{(j)}$ through [55, (4)], here

$$x^{(j+1)} = x^{(j)} - \frac{H_n(x^{(j)})}{H'_n(x^{(j)})} \left[1 + x^{(j)} \frac{H_n(x^{(j)})}{H'_n(x^{(j)})} \right]. \quad (\text{C1})$$

Note two sign errors in [55, (3)]; the correct equation is

$$\begin{aligned} \alpha &= x - f/f' - (P + S/f')(f/f')^2 \\ &\quad - \frac{1}{3}(4P^2 - P' + Q + 10PS/f' - S'/f' + 6S^2/f'^2)(f/f')^3 + O[(f/f')^4]. \end{aligned} \quad (\text{C2})$$

Similar to [54, (5.10)] one might consider using the terminating continued fraction

$$\frac{H'_n(x)}{H_n(x)} = \frac{2n}{2x-} \frac{2(n-1)}{2x-} \frac{2(n-2)}{2x-} \dots \frac{2}{2x} = \frac{n}{x-} \frac{(n-1)}{2x-} \frac{(n-2)}{x-} \frac{(n-3)}{2x-} \dots. \quad (\text{C3})$$

in (C1) to meet the thread of cancellation of digits. The weights follow as [19, (25.4.46)]

$$\lambda_k^{(n)} = \frac{2^{n-1}n!\sqrt{\pi}}{n^2[H_{n-1}(t_k^{(n)})]^2}. \quad (\text{C4})$$

APPENDIX D: “PERTURBED” QUADRATURE

Eq. (47) is an application of the Euler-Mclaurin formula [19, (25.4.7)]

$$\int_a^b f(x)dx = (b-a)\frac{f(a)+f(b)}{2} - \frac{(b-a)^2}{12}[f'(b)-f'(a)]. \quad (\text{D1})$$

This is in contrast to a rule that involves the value in the midpoint of the integration intervals [56, (2)]:

$$\int_a^b f(x)dx = (b-a)f\left(\frac{a+b}{2}\right) + \frac{(b-a)^2}{24}[f'(b)-f'(a)]. \quad (\text{D2})$$

The evaluation of the function at the end points a and b in Sect. VIE is cheaper than an additional evaluation in the middle of the integration interval, because it needs two complex multiplications but no new exponentials. So the midpoint rule and variants proposed by Hammer and Wicke [57, 58, 59, 60] are not advantageous in our case. A cubic spline interpolation $f(x) = \sum_{n=0}^3 c_n x^n$ induces the higher moments

$$\begin{aligned} \int_a^b x f(x)dx &= \frac{b-a}{60} \left\{ a^2 [2f'(b) - 3f'(a)] + a [bf'(b) + 9f(b) + 21f(a) + bf'(a)] \right. \\ &\quad \left. + 2b^2 f'(a) + 21bf(b) + 9bf(a) - 3b^2 f'(b) \right\}, \end{aligned} \quad (\text{D3})$$

$$\int_a^b x^2 f(x) dx = \frac{b-a}{60} \left\{ a^3 [f'(b) - 2f'(a)] + a^2 [bf'(b) + 4f(b) + 16f(a)] \right. \\ \left. + ab [bf'(a) + 10f(b) + 10f(a)] \right. \\ \left. + b^2 [4f(a) - 2bf'(b) + 16f(b) + bf'(a)] \right\}, \quad (\text{D4})$$

which establishes (48), and

$$\int_a^b x^3 f(x) dx = \frac{b-a}{420} \left\{ a^4 [4f'(b) - 10f'(a)] + a^3 [5bf'(b) + 90f(a) - 2bf'(a) + 15f(b)] \right. \\ \left. + 3a^2b [bf'(b) + 13f(b) + bf'(a) + 22f(a)] \right. \\ \left. + ab^2 [66f(b) + 39f(a) + 5bf'(a) - 2bf'(b)] \right. \\ \left. + b^3 [-10bf'(b) + 4bf'(a) + 15f(a) + 90f(b)] \right\}. \quad (\text{D5})$$

$$\int_a^b x^4 f(x) dx = \frac{b-a}{840} \left\{ a^5 [5f'(b) - 15f'(a)] + a^4 [7bf'(b) + 150f(a) - 5bf'(a) + 18f(b)] \right. \\ \left. + 2a^3b [3bf'(b) + 24f(b) + bf'(a) + 60f(a)] \right. \\ \left. + 2a^2b^2 [42f(b) + 42f(a) + 3bf'(a) + bf'(b)] \right. \\ \left. + ab^3 [-5bf'(b) + 48f(a) + 7bf'(a) + 120f(b)] \right. \\ \left. + b^4 [-15bf'(b) + 5bf'(a) + 18f(a) + 150f(b)] \right\}. \quad (\text{D6})$$

The generalization of (D1) to an integral over a quintic spline that engages also the second derivatives (curvatures) at the interval limits reads

$$\int_a^b f(x) dx = (b-a) \frac{f(a) + f(b)}{2} - \frac{(b-a)^2}{10} [f'(b) - f'(a)] + \frac{(b-a)^3}{120} [f''(b) + f''(a)], \quad (\text{D7})$$

which simplifies to (D1) if $f(x)$ is any cubic polynomial. The three formulas (D5)–(D7) have not been used in this work.

APPENDIX E: GAUSS-JACOBI ABSCISSAE AND WEIGHTS

Formulas of weights w_i and abscissae t_i with (44) are given in [19, (25.4.33)], where t_i are the zeros of Jacobi Polynomials $P_n^{(2m,0)}(1-2t)$, and

$$1/w_i = \sum_{j=0}^{n-1} (2m+2j+1) [P_j^{(2m,0)}(1-2t_i)]^2. \quad (\text{E1})$$

If $m = 0$, this reduces to the Gauss-Legendre quadrature, Table 25.4 in [19]. Table 25.8 in [19] covers the cases $m \leq 2$ with $n \leq 8$, and we provide Tables VI–VII to cover $2m \equiv k = 2$ or 4 with $n = 20$.
